(54) Title: METHOD FOR PRODUCING ZEOLITES AND ZEOTYPES

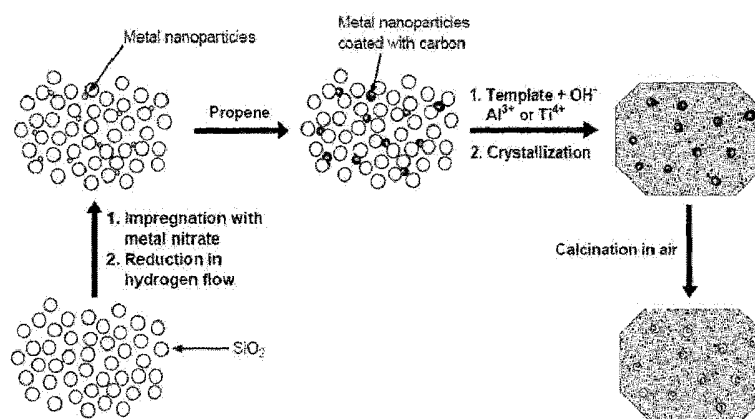

Fig. 2b

(57) Abstract: The invention relates to a method for producing zeolite, zeolite-like or zeotype particles comprising the steps of: 1 ) Adding one or more metal precursors to a silica or alumina source; 2) Reducing the one or more metal precursors to form metal nanoparticles on the surface of the silica or alumina source; 3) Passing a gaseous hydrocarbon, alkyl alcohol or alkyl ether over the silica or alumina supported metal nanoparticle to form a carbon template coated zeolite, zeolite-like or zeotype precursor composition; 4a) Adding a structure directing agent to the carbon template coated zeolite, zeolite-like or zeotype precursor composition thereby creating a zeolite, zeolite-like or zeotype gel composition; 4b) Crystallising the zeolite, zeolite-like or zeotype gel composition by subjecting said composition to a hydrothermal treatment; 5) Removing the carbon template and structure directing agent and isolating the resulting zeolite, zeolite-like or zeotype particles.

## Method for producing zeolites and zeotypes

### Field of the invention

The invention concerns a method for making zeolites and zeotypes and the zeolites  
5 and zeotypes produced by the method.

### Background of the invention

Zeolites are crystalline alumina silicate materials that exhibit a highly ordered porous structure with pores of molecular diameter. IUPAC identifies this type of porosity as  
10 microporous, as the size of the pores are not wider than 2 nm. The other groups of porosity are mesoporous (pore size between 2–50 nm) and macroporous (pore size larger than 50 nm). Zeolites consist of tetrahedral  $\text{TO}_4$  units ( $\text{T} = \text{Si}$  or  $\text{Al}$ ), which gives the framework an overall composition of  $\text{TO}_2$ . These materials have a clear organized framework throughout the crystals, giving rise to highly ordered pores and  
15 a large internal surface area. By replacing a silicon atom with an aluminium atom, it is possible to generate a deficit of charge, which is compensated by a cation located nearby. The cation is usually an alkali metal (such as sodium), alkali earth metal, or possibly a  $\text{H}^+$  ion. If the cation is a proton, the zeolite becomes a strong Brønsted acid. All these characteristics give rise to a lot of uses for zeolites. These  
20 applications range from ion exchangers in laundry detergent powder to adsorbent agents and as catalysts, often as solid acid catalyst due to the Brønsted acid sites. Their catalytic applications range from fluid catalytic cracking (FCC), petrochemistry and the synthesis of special chemicals to environmental catalysis.

25 Today, nearly 60 different natural occurring zeolites are known, while 201 can be prepared synthetically [1]. These zeolites have different structures, due to different Si-O-Al linkages, and a different number of Si or Al atoms linked in each “cage”. This also creates different pore system of one-, two, or three-dimensions in the zeolite. As the pores are very regular, and around the same size in diameter as molecules, it  
30 is possible for zeolites to function as molecular sieves. Due to their chemical structure and molecular sieve properties, zeolite catalysts exhibit high selectivity for a variety of chemical reactions. Since most of the surface area and the active sites are within the zeolite, the shape of the pores and channels give rise to shape

selective catalysis. Commonly there is distinguished between three types of molecular sieving effects:

- 1) Reactant shape selectivity: Only molecules small enough can enter the zeolite pores and undergo chemical transformation or be adsorbed.
- 2) Product shape selectivity: The size of the pores is too small, that not all possible products can diffuse out of the zeolite after reaction. This leads to an increased selectivity towards smaller molecules or isomers.
- 3) Restricted transition-state shape selectivity: Here the formation of too large transition state intermediates are prevented due to zeolite pore size. Figure 1 illustrates the three different kinds of shape selectivity.

#### Zeolite Synthesis

In general, zeolite synthesis is a crystallization process, where silica and alumina species dissolve and react to give a less soluble crystalline alumina/silicate product. The crystallization process is typically performed in a hydrothermal process where these zeolite precursors are added to an autoclave and heated to relatively high temperatures and autogenous pressures. The high pressure is due to the evaporation of water inside the autoclave, and is very important for the synthesis. In a typical synthesis the zeolite precursors are dissolved or suspended in an aqueous solution of a structure directing agent (SDA) and an alkali hydroxide to catalyze the breaking and formation of chemical bonds [4].

The structure directing agents are almost always organic amine cations. Some of the most commonly used organic structure directing agents are tetramethylammonium (TMA), tetraethylammonium (TEA), and tetrapropylammonium (TPA), though compounds as diverse as Choline, 1,6-diaminohexane, and hexanediol have been used. During the zeolite crystallization process, the zeolites form around molecules of the structure directing agent. The shape and properties of the structure directing agent causes the zeolites forming around it to take a certain shape. Stoichiometric analysis of samples of ZSM-5 has indicated that one  $\text{TPA}^+$  molecule occupies each intersection between pores in the zeolite [2].

For sources of silicon, mostly sodium silicate, fumed silica or tetraethoxy ortho-silicate are used, while sodium aluminate, aluminum nitrate or –chloride are typical sources of aluminum [3]. The mixture of zeolite precursors (amorphous zeolite gel) is then transferred to an autoclave and heated to a predetermined temperature, often between 120-200 °C. Within days, possibly weeks, the precursors begin to crystallize and form the zeolite. After the synthesis, the autoclave is cooled to room temperature, and the zeolite material is washed with water and isolated by filtration or centrifugation. The zeolite is then calcined at around 500-600 °C to remove residual SDA and framework water. At last the zeolite can be ion exchanged. This can either be done to introduce hydrons, alkali metal, alkali earth metal, lanthanoid or transition metal cations.

In 1983 Taramasso et al. incorporated titanium ions into silicalite-1 (denominated as TS-1) [56]. The incorporation of titanium is an isomorphous substitution in the MFI lattice of the silicalite-1. The presence of a titanium atom gave rise to different catalytic properties than the selective acid catalytic properties displayed by conventional alumina silicate zeolites. The TS-1 has been found useful in selective oxidation reactions, such as the hydroxylation of phenols, epoxidation of alkenes, and ammoxidation of ketones [57–61].

#### Diffusion in Zeolites

The microporous structure of zeolites does not only determine the chemical selectivity, but also play an important role concerning mass transport within the zeolite crystal. The micropores can limit the diffusion, molecular mobility and ultimately determine the reaction rate of the overall process [6, 7]. In addition, slow diffusion can cause polymerization of by-products or reaction intermediates blocking catalytic active sites within the microporous channels. For some catalytic applications this may lead to severe deactivation [8]. In the case of zeolites with unidirectional channels, the diffusion can be sharply reduced by small amounts of debris in the pores generated during zeolite synthesis or activation and by small amounts of strongly adsorbed molecules.

These problems are smaller in zeolites in which a bidirectional or tridirectional pore system is present [9]. By synthesising zeolites with extra-large pores, it is possible to

overcome some of these mass transfer limitations. These materials are often synthesised using bulky organic amines as a pore-generating agent [10–14]. However, the unfavourable thermal stability of large pored zeolites, in combination with the high cost of these organic templates for the synthesis [14–17] hampers their use. In addition, the large unimodal mesopore system of these zeolites will not exhibit the same shape selectivity as the microporous zeolites.

Another way to improve the diffusivity is by using ordered mesoporous materials, e.g. MCM-41 and SBA-15. These silica composites contains large and uniform pores, which has proven to be effective concerning the molecular diffusion and mass transfer problems associated with conventional zeolites. These materials have shown an increased catalytic activity compared to conventional zeolites [18]. However, due to the amorphous nature of these materials, they exhibit low thermal and mechanical stability [7, 19] as well as weaker acidity compared to conventional zeolites. These drawbacks severely limit the catalytic application of both extra-large pored zeolites and ordered mesoporous materials and other possibilities must be examined.

In order to improve accessibility to the catalytically active sites in the micropores of zeolites, without losing shape selectivity and stability, much effort has been devoted to the development of hierarchical zeolites. Hierarchical zeolites are characterised by porosity in the meso- or macropore range in addition to the micropores [7]. The reason for the increased interest in these materials, is the addition of the improved transport due to the interconnections of a secondary network of inter- or intracrystalline mesopores, while still maintaining the catalytic properties (shape selectivity and hydrothermal stability) associated with the conventional zeolite. Three overall hierarchical zeolite types exist:

- 1) Nanosized Zeolites are zeolites that exhibits intercrystalline voids or pores, in addition to the micropores present in the zeolites.
- 2) Composite Zeolites are zeolites supported on a material that is typically meso- or macroporous. Here, the support is facilitating the mass transport.
- 3) Meso- or macroporous Zeolites are zeolites where the additional porosity has been introduced by demetallation or by using an organic template.

Mesoporous zeolites are characterized by having connected intracrystalline meso- and micropores. The micropores originate from the conventional synthesis of zeolites, but the mesopores can be introduced in numerous ways. Overall, there are two distinctive methods to produce a mesoporous system inside a zeolite: Non-templating and templating methods. Demetallation is a non-templating method and involves dissolving part of a conventional zeolite by the use of a chemical reagent. The conditions are typically quite harsh, involving strong acids, bases, hot steam or complexing agents, as zeolites are highly stable. Regarding the templating procedures, several types of templates have been utilised for the introduction of mesopores in zeolites. These are grouped into two groups, depending on the interface between the zeolite crystal and the template.

Soft templating is the use of e.g. surfactants to generate porosity. One method is to add a surfactant to the zeolite synthesis gel. This facilitates the assembly of a mesostructured phase from the zeolite seed solution [35, 36]. After the hydrothermal synthesis the soft template is removed by combustion together with the SDA.

Hard templating applies a solid material to generate the mesopore system. This method has proved to be very effective and a highly versatile approach. Templates include organic aerogels, polymers, and carbon in different forms. Here, only carbon templates will be mentioned. One of the well-known methods is the crystallization of zeolite gel in porous carbon particles. If the amount of synthesis gel relative to the carbon template is sufficient, the zeolite crystals continue to grow after nucleation in the cavities of the carbon. This will allow the zeolite crystal to encapsulate the carbon. Combustion of the carbon particles embedded in the zeolite crystal, will lead to the formation of mesopores [37]. Several types of carbon nanoparticles have been used [38], including carbon nanotubes [39] and nanofibers.

As a carbon source it is also possible to apply in situ prepared carbon, typically by carbonization of various precursors. This has been done by e.g. decomposition of various precursors in the pores of ordered mesoporous materials such as MCM-41. The mesoporous material is then dissolved and the resulting carbon is impregnated with the zeolite synthesis gel. After crystallisation and combustion of the carbon,

mesoporous zeolite is obtained [40]. Kustova et al. [41] reported a similar synthesis method, only with the use of cheap silica and sucrose as silicon and carbon precursors. This resulted in a crystalline mesoporous zeolite.

- 5 Despite the obvious advantages of mesoporous zeolites compared to conventional zeolites, it is not without disadvantages. Introducing mesoporosity in zeolites will cause an increasing portion of the active sites to be available for molecules too large to actually enter the micropore structure. It has been shown, that 2,4-
- 10 dimethylpyridine probes approximately half the Brønsted acidic sites in a commercial ZSM-5 sample vs. nearly 100% after a strong desilication [54]. In addition the mesopore walls can also be catalytically active [55], allowing the inclusion and catalysis of bulky molecules. This means that shape selectivity of mesoporous zeolites will be reduced compared to microporous zeolites. The design of the mesoporous zeolite must therefore be carefully considered, before it is
- 15 applied to a given reaction.

Despite the growing demand, a fast, efficient and economically feasible process for synthesising mesoporous zeolites or zeotypes (ie. artificial materials based on the structure of zeolites) that can be scaled up for industrial application has not yet been

20 reported.

### Summary of the invention

The present invention relates to a method for producing zeolite, zeolite-like or zeotype particles comprising the steps of:

- 25 1) Adding one or more metal precursors to a silica or alumina source;
- 2) Reducing the one or more metal precursors to form metal nanoparticles on the surface of the silica or alumina source;
- 3) Passing a gaseous hydrocarbon, alkyl alcohol or alkyl ether over the silica or alumina supported metal nanoparticle to form a carbon template coated zeolite,
- 30 zeolite-like or zeotype precursor composition;
- 4a) Adding a structure directing agent to the carbon template coated zeolite, zeolite-like or zeotype precursor composition thereby creating a zeolite, zeolite-like or zeotype gel composition;

- 4b) Crystallising the zeolite, zeolite-like or zeotype gel composition by subjecting said composition to a hydrothermal treatment;
- 5) Removing the carbon template and structure directing agent and isolating the resulting zeolite, zeolite-like or zeotype particles.

5

The present invention also relates to a zeolite, zeolite-like or zeotype particle manufactured by the method according to the present invention with a crystal structure comprising one or more encapsulated metal nanoparticles.

30

### Detailed description of the invention

In the following detailed description of the invention, reference is made to the examples, including tables and figures.

In this application a method to produce zeolites, zeolite-like and zeotypes through a carbon-templating process is presented. This is a new method to synthesize mesoporous zeolite and zeotype materials and stands out from previously reported methods [62, 76–78] because the carbon template is generated by a direct coking process facilitated by pre-formed metal nanoparticles on the silica/aluminium source.

- The invention relates to a method for producing zeolite, zeolite-like or zeotype particles comprising the steps of:
- 1) Adding one or more metal precursors to a silica or alumina source;
  - 2) Reducing the one or more metal precursors to form metal nanoparticles on the surface of the silica or alumina source;
  - 3) Passing a gaseous hydrocarbon, alkyl alcohol or alkyl ether over the silica or alumina supported metal nanoparticle to form a carbon template coated zeolite, zeolite-like or zeotype precursor composition;
  - 4a) Adding a structure directing agent to the carbon template coated zeolite, zeolite-like or zeotype precursor composition thereby creating a zeolite, zeolite-like or zeotype gel composition;
  - 4b) Crystallising the zeolite, zeolite-like or zeotype gel composition by subjecting said composition to a hydrothermal treatment;
  - 5) Removing the carbon template and structure directing agent and isolating the resulting zeolite, zeolite-like or zeotype particles.

Different zeolite structures (framework) are suitable for the above method of production. The zeolite structure can be zeolite beta (BEA), Y (FAU), ZSM-5 (MFI), ZSM-11 (MEL) or ZSM-12 (MTW).

The method is based on carbon templating (like the sucrose method [41]) but originates from the desire to develop a fast, efficient and cheap method that can be scaled up for industrial application. An overview of this synthesis is presented in Figure 2b.

Throughout the description, when zeolites is mentioned it is meant to comprises zeolites, zeolite-like materials and zeotypes unless other is specifically mentioned.

By the term zeolite-like is meant non-silicon comprising material. Examples of zeolite-like materials are non-silicon comprising materials such as aluminium phosphate ( $\text{AlPO}_4$ ) molecular sieves, known as AIPO's. The phosphorous  
5 compound can be selected from the group consisting of phosphoric acid, phosphate salts and mixtures thereof. By the term "phosphate salts" is meant salts of phosphates, monohydrogen phosphates and dihydrogen phosphates.

By zeolite, zeolite-like and zeotype particle is also meant zeolite, zeolite-like and  
10 zeotype crystal or zeolite, zeolite-like and zeotype material.

By metal nanoparticles is also meant metal oxide nanoparticles and metal nitrate nanoparticles. The metal or mixture of metal precursors might form into the respective oxides or nitrates. This can happen either during the manufacturing  
15 process or in the end product

Possible silica sources for zeolites may be bulk silica of different quality and alumina contamination, including pure silica, fumed silica, sodium silicate or precipitated silica, tetraethyl orthosilicate ect.  
20

Possible aluminium sources for zeolites may be aluminum nitrate, aluminum sulphate, aluminum phosphate, sodium aluminate ect.

A hydrothermal process is a technique of crystallizing substances from high-  
25 temperature aqueous solutions at high vapour pressure.

The inherent micropores in the zeolite structure are also here called primary porosity whereas the ekstra pores created by the method of the present invention are referred to as secondary porosity. This secondary porosity can both be micropores  
30 or mesopores.

The first step in the process is to add one or more metal precursors to a silica/alumina source.

In one or more embodiments, the first step is performed at room temperature.

In one or more embodiments, the first step is performed at elevated temperatures such as from 50°C to 150°C, such as around 80°C.

5

The metal precursors can be added by grinding, impregnation, co-precipitation, deposition-precipitation or chemical vapor deposition.

10 Impregnation: a solution, e.g. an aqueous or alcoholic solution of one or several transition metal precursors is applied to a silica/alumina source. The solution is dried, e.g. in an oven at 80°C overnight, whereby water is evaporated and left is the metal on the surface of the silica/alumina source.

15 Deposition Precipitation: silica and the one or more metal precursors are mixed together in a solution. By changing pH or adding chemicals, e.g. H<sub>2</sub>O<sub>2</sub>, the character of the metal change to another compound and deposit on the silica.

20 Chemical Vapour Deposition: The metal or mixture of metals can be in a gas phase or liquid phase. If the metal is in a liquid phase the liquid is heated to the boiling point and passed over the silica where it is deposited. If the metal is in the gas phase, the gas is passed over the silica where it is deposited.

In one embodiment nickel particles are made volatile by CO and carbonyl compound are created, which are deposited on the silica and creates carbon nanotubes.

25

In one embodiment of the method the one or more metal(s) is selected from the group consisting of group 4 elements, group 6 elements, group 7 elements, group 8 elements, group 9 elements, group 10 elements, group 11 elements or group 12 elements or mixtures thereof. The group elements are defined by the new IUPAC  
30 numbering.

In one embodiment of the method the one or more metal(s) is selected from the group consisting of titanium, osmium, iridium, platinum, ruthenium, palladium,

rhodium, rhenium, copper, nickel, iron, cobalt, silver, gold, cadmium, molybdenum or mixtures thereof. In one embodiment the metal is nickel.

5 In one embodiment of the method step 1 is performed in a liquid phase, e.g. in an aqueous or alcoholic solution, in a gas phase or in a solid phase. The aqueous or alcoholic solution of the one or more metal precursors could comprise nitrates, carbonates, acetates sulphates or chlorides.

10 In one embodiment, **the first step** in the process involves impregnating a silica or alumina precursor with an aqueous or alcoholic solution of one or several transition metal precursors. The possible metals especially include Fe, Co, Ni, Cu, Ru, Rh, Pd, Ag, Pt, Au, Mo, and mixtures thereof. The possible metal precursors include nitrates, carbonates, acetates, sulfates, chlorides and carbonyls.

15 The possible metal can also be metal alloy such as gold-platinum, copper-palladium, ruthenium-copper, platinum-iridium, platinum-palladium, platinum-ruthenium, cobalt-molybdenum, nickel-molybdenum, or palladium-gold, where one of the metals in the metal alloy can be present in an amount of from 1 to 50%. The optimal weight ratio between the metals in the alloy depends on the metal alloy.

20 **The second step** in the process involves reducing the one or more metal precursors to form metal nanoparticles on the surface of the silica or alumina source. The metal precursors are reduced in a reducing atmosphere, for instance in a stream of hydrogen, or decomposed by a thermal treatment to give the  
25 corresponding transition metal nanoparticles. The transition metal nanoparticles can also be in the form of metal oxide nanoparticles or metal nitrate nanoparticles. This reduction step is in one embodiment performed at elevated temperatures, e.g. from 200 to 800 °C such as from 200 to 700 °C, or such as from 200 to 600 °C.

30 **The third step** in the process involves passing a gaseous hydrocarbon, alkyl alcohol or alkyl ether over the silica/alumina source with the impregnated metal nanoparticles, thereby forming a zeolite precursor composition comprising carbon coated metal nanoparticles. The physical shape of the the thus deposited carbon (also called carbon template) coating the nanoparticles can vary depending on the

process conditions. In one embodiment the carbon is in the form of whiskers (nanotubes). In another embodiment the carbon is in the form of nanofibers. In another embodiment the carbon is in the form of spheres encircling the metal nanoparticles.

5

In one embodiment the flow of gaseous hydrocarbon, alkyl alcohol or alkyl ether is in the range of 20 to 500 ml/min, 20 to 400 ml/min, 100 to 400 ml/min, 30 to 100 ml/min, 50 to 90 ml/min, 50 to 70 ml/min or 60 to 70 ml/min.

- 10 In one embodiment, the third step of the process involves heating the silica or alumina and metal nanoparticles to 200-1100°C, such as from 200-800°C, or from 300-1100°C.

- 15 In separate embodiments the hydrocarbon is selected from aliphatic hydrocarbons having 1 to 8 carbon atoms, having 1 to 3 carbon atoms, alkenes having 2 to 6 carbon atoms, aromatic hydrocarbons having 6 to 10 carbon atoms and cyclic hydrocarbons having 3 to 8 carbon atoms.

- 20 In a specific embodiment the hydrocarbon is selected from methane, propene, xylene or benzene.

In other separate embodiments the alkyl alcohol is selected from aliphatic alcohols having 1 to 8 carbon atoms, or having 1 to 3 carbon atoms.

- 25 In other separate embodiments the alkyl ether is selected from aliphatic ethers having 2 to 8 carbon atoms, or having 2 to 4 carbon atoms.

In a specific embodiment the alkyl ether is DME (dimethylether).

- 30 In one embodiment the flow of gaseous hydrocarbon, alkyl alcohol or alkyl ether is applied for around 1-5 hours e.g. 2 hours.

In a specific embodiment, the third step of the process involves heating the silica or alumina and metal nanoparticles to 300-1100°C in a stream of a simple hydrocarbon

gas (1-8 carbon atoms or cyclic hydrocarbons) that decomposes on the metal surface to leave the carbon template deposited on the zeolite precursor composition.

- 5     **The fourth step** involves two steps; step 4a is adding a structure directing agent to the carbon template coated zeolite, zeolite-like or zeotype precursor composition thereby creating a zeolite, zeolite-like or zeotype gel composition; and step 4b is crystallization of the zeolite, zeolite-like or zeotype gel composition by subjecting the zeolite, zeolite-like or zeotype gel composition to a hydrothermal treatment.

10

During this step 4, the silica or alumina is dissolved in an aqueous alkaline media creating a supersaturated solution from which the zeolite is formed around the carbon template in the presence of a structure directing agent (SDA), preferably a quaternary ammonium salt such as TPAOH (tetrapropylammonium hydroxide) or  
15     TBAOH (tetrabutylammonium hydroxide). This creates an initial, amorphous zeolite gel, which in a subsequent hydrothermal step is transformed into the crystalline zeolite. The hydrothermal process is often performed under elevated temperatures between 70 and 300 °C, preferably at 180 °C, and autogeneous pressure in an autoclave or open flask for 24 hours or more.

20

In one or more embodiments, the carbon template coated zeolite, zeolite-like or zeotype precursor composition of step 3 is used directly in step 4a without removing the silica or alumina source. In this way, the silica or alumina source is reused in the following process, which reduces the production cost compared to alternative  
25     processes, where it is removed and only the carbon skeleton is used in the further process as seen in e.g. A. H. Janssen et al, Microporous and Mesoporous Materials 65 (2003), page 59-75. Further, by reusing the silica or alumina source, the method is simplified.

- 30     In a specific embodiment, the fourth step comprises a hydrothermal treatment of an initially formed zeolite gel wherein the gel is heated to temperatures between 70 and 300 °C, preferably at 180 °C. In addition it may be under an autogeneous pressure in an autoclave or open flask for 24 hours or more.

In one embodiment the method of producing a zeolite or zeotype particle comprises adding an Al, Sn, Ti, Zr or Ge source during step 4a. The source may be an  $\text{Al}^{3+}$ ,  $\text{Sn}^{2+}$ ,  $\text{Sn}^{4+}$ ,  $\text{Ti}^{4+}$ , Zr or Ge source.

5 Sources of Titanium could be e.g. titanium chlorides, titanium sulphates, titanium alkoxides e.g. TEOT (tetraethyl orthotitanate) and TBOT (tetrabutyl orthotitanate). Sources of aluminium could be aluminum nitrate, aluminum sulphate, aluminum phosphate, sodium aluminate ect. Sources of tin could be tin chlorides, tin oxides or splid tin dissolved in hydrochloric acid. Sources of zirconia could be zirconia chloride  
10 or zirconia oxide. If an aluminium source was used in step 1 in the process instead of a silica source, then a silica source should be applied at this step. The source of silica is bulk silica of different quality and alumina contamination, including pure silica, fumed silica, sodium silicate or other soluble silicate salts, precipitated silica, tetraethyl orthosilicate and other alkoxy-silicates, silicic acid, etc.

15 The source of  $\text{Al}^{3+}$ ,  $\text{Sn}^{2+}$ ,  $\text{Sn}^{4+}$ ,  $\text{Ti}^{4+}$ , Zr or Ge will be part of the framework in the crystal structure. Therefore, Ti-zeotype particles, Sn-zeotype particle, Zr-zeotype particle or Ge-zeotype particles can be manufactured by the present method.

20 **In the fifth step** the catalyst is washed, dried and calcined in air at above 300 °C, preferably between 300-700 °C, preferably between 400-700 °C to remove the structure directing agent and the carbon template. Calcination triggers thermal decomposition of the structure directing agent leaving the zeolite behind. More preferably a controlled combustion is conducted by calcination of the crystalized  
25 zeolite in air at 550 °C. The combustion is conducted for e.g. 24 hours or 20 hours. The combustion can also be conducted for more than 24 hours. Upon removal of the carbon template by calcination, the zeolite crystals obtain a secondary porosity in addition to the inherent zeolite microporous system. The porosity can be modified by changing the type and amount of carbon.

30 According to the present invention, the metal nanoparticles previously supporting the growth of carbon templates (whiskers, nanotubes etc) during the third step of the process are left behind in the secondary porosity of the zeolites after the fifth step has been carried out. These metal nanoparticles are homogeneously distributed

throughout the crystalline zeolite structure and are further individually shielded from physical contact with other metal nanoparticles hosted in the zeolite by the walls of the formed pores.

- 5     The calcination procedure conducted in step 5 is expected to remove the carbon template and remaining amounts of the structure directing agent. However, under certain combinations of reaction parameters the zeolite structure may still contain traces of carbon trapped in pores.
- 10    In the following one possible method is outlined. The first step involves impregnating an aqueous solution of a metal nitrate on the silica. The metal nitrate is then reduced in a hydrogen stream to form metal nanoparticles. Subsequently, the hydrogen gas flow is stopped and a gaseous hydrocarbon, e.g. propene gas is passed over the sample. Depending on the nature of the metal nanoparticles, the
- 15    time of exposure to the hydrocarbon gas, the temperature, the nature of the carbon gas, e.g. propene may cover and encapsulate the metal nanoparticles or deposit as carbon [42, 43]. More carbon will result in more and larger mesopores being formed in the final catalyst. After this procedure, the zeolite precursor is mixed with a structuring directing agent (SDA) and a base and put in a Teflon beaker inside a
- 20    Teflon-lined autoclave containing a sufficient amount of water to generate saturated steam and heated to e.g. 180 °C for e.g. 72 hours. After the hydrothermal treatment, the carbon template is removed by combustion. This will lead to uniformed micropores or mesopores in the zeolite, which are modifiable by increasing or decreasing the nanoparticle size. After the synthesis, the metal nanoparticles may
- 25    still be present inside the catalyst. These can be removed (e.g. nickel is possible to form soluble complexes with cyanide and amines [44]).

In one embodiment of the method the carbon template is shaped as carbon nanotubes.

30

Carbon formation in the form of whisker carbon is a very common phenomenon with e.g. nickel nanoparticles [42, 43]. This may result in a larger amount of carbon formation than expected if the nanoparticles were simply encapsulated. The length,

width and amount of carbon, e.g. in the form of whiskers, can be tuned by changing the different parameters, such as gas, temperature and time.

5 In one embodiment of the method the one or more metal precursors is added to the silica in an amount of 5 to 20 wt %, from 0.5 to 5 wt %, from 0.5 to 2 wt %, or around 1 wt % during step 1.

10 In one embodiment of the method the zeolite precursor has a carbon-to-silica ratio of from 0.30 to 2.00 w/w, 0.30 to 1.00 w/w, 1.00 to 2.00 w/w or from 0.34 to 0.75 w/w.

In one embodiment of the method the zeolite precursor has a carbon-to-alumina ratio of from 0.30 to 2.00 w/w, 0.30 to 1.00 w/w, 1.00 to 2.00 w/w or from 0.34 to 0.75 w/w.

15 By the present invention, zeolites with a nickel content of 1 wt% were successfully synthesised with consistent size and shape of 1.0-2.5  $\mu\text{m}$ . Mesopores which were visible by SEM were produced and nitrogen physisorption confirmed the presence of mesopores with a pore width of approximately 20 nm, and a microporous system with widths of approximately 2 nm. The size of the pores produced in the zeolite  
20 according to the present invention were similar to the ones obtained for the mesoporous TS-1, prepared with BP 2000. Overall, the volume of the mesopores and the external surface area for the nickel prepared sample, were greater than the conventional TS-1. EDS analysis of the calcined zeolite showed presence of nickel, titanium, oxygen and silicon.

25 The present invention also relates to a zeolite, zeolite-like or zeotype particle manufactured by the method according to the present invention with a crystal structure comprising one or more encapsulated metal nanoparticles.

30 In one embodiment the zeolite, zeolite-like or zeotype particle is a hierarchical mesoporous zeolite, zeolite-like or zeotype particle.

In one embodiment the one or more encapsulated metal nanoparticles comprise one or more metal(s) selected from the group consisting of group 4 elements, group 6

elements, group 7 elements, group 8 elements, group 9 elements, group 10 elements, group 11 elements or group 12 elements or mixtures thereof. The group elements are defined by the new IUPAC numbering.

- 5 In one embodiment the one or more encapsulated metal nanoparticles comprise one or more metal(s) is selected from the group consisting of titanium, osmium, iridium, platinum, ruthenium, palladium, rhodium, rhenium, copper, nickel, iron, cobalt, silver, gold, cadmium, molybdenum or mixtures thereof. In one embodiment the metal is nickel.

10

In one embodiment the particles comprises mesopores in the range from 2 to 50 nm, from 5 to 30 nm, from 10 to 25 nm, from 15 to 25 nm, from 18 to 22 nm, from 19 to 21 nm or around 20 nm. In one embodiment the particles comprises mesopores having sizes around 10 nm.

15

In one embodiment the zeolite particles comprises micropores in the range from 0.1 to 2 nm, from 1 to 2 nm or around 2 nm.

- 20 In one embodiment the zeolite, zeolite-like or zeotype particle comprise an Al, Sn, Ti, Zr or Ge source in the framework of the crystal structure. The source may be an  $\text{Al}^{3+}$ ,  $\text{Sn}^{2+}$ ,  $\text{Sn}^{4+}$ ,  $\text{Ti}^{4+}$ , Zr or Ge source. The source of  $\text{Al}^{3+}$ ,  $\text{Sn}^{2+}$ ,  $\text{Sn}^{4+}$ ,  $\text{Ti}^{4+}$ , Zr or Ge will be part of the framework in the crystal structure. Therefore, the invention also comprises Ti-zeotype particles, Sn-zeotype particle, Zr-zeotype particle or Ge-zeotype particles manufactured by the present method.

25

In one embodiment the amount of metal nanoparticles are in the range of 0.1 to 25 wt%, in the range from 0.5 to 20 wt%, from 0.5 to 10 wt%, from 0.5 to 5%, from 1.0 to 5 wt %, from 1 to 2 wt %, or around 1 wt %.

- 30 The amount of metal nanoparticles in the crystallised zeolite structure is preferably more than 80% of the metal loading.

In one embodiment the zeolite, zeolite-like or zeotype particle has a  $V_p$  value in the range of 0.300 to 0.500 cm<sup>3</sup>/g, 0.300 to 0.400 cm<sup>3</sup>/g or around 0.320 cm<sup>3</sup>/g, or around 0.450 cm<sup>3</sup>/g.

- 5 In one embodiment the zeolite, zeolite-like or zeotype particle has an external surface area in the range of 100-400 m<sup>2</sup>/g, or around 170 to 200 m<sup>2</sup>/g or around 190 m<sup>2</sup>/g.

- 10 In one embodiment the zeolite, zeolite-like or zeotype particle has a BET surface area of 300 to 500 m<sup>2</sup>/g or 350 to 400 m<sup>2</sup>/g,

**The size of the crystal structure is in the range of 1.0 to 2.5  $\mu$ m.**

- 15 The present invention also comprises hierarchical mesoporous zeolites, zeolite-like or zeotype particles comprising one or more encapsulated metal nanoparticles. The particles may comprise mesopores in the range from 2 to 50 nm, from 5 to 30 nm, from 10 to 25 nm, from 15 to 25 nm, from 18 to 22 nm, from 19 to 21 nm or around 20 nm. In one embodiment the particles comprises mesopores having sizes around 10 nm. The micropores are in the range from 0.1 to 2 nm, from 1 to 2 nm or around 20 2 nm.

- In one embodiment the one or more encapsulated metal nanoparticles comprise one or more metal(s) selected from the group consisting of group 4 elements, group 6 elements, group 7 elements, group 8 elements, group 9 elements, group 10 elements, group 11 elements or group 12 elements or mixtures thereof. The group elements are defined by the new IUPAC numbering.
- 25

- In one embodiment the one or more encapsulated metal nanoparticles comprise one or more metal(s) selected from the group consisting of titanium, osmium, iridium, platinum, ruthenium, palladium, rhodium, rhenium, copper, nickel, iron, cobalt, silver, gold, cadmium, molybdenum or mixtures thereof. In one embodiment the metal is nickel.
- 30

The zeolites produced according to the present invention can be used in the selective oxidation of tertiary amines to N-oxides.

5 The present invention also comprises the use of the zeolite particles according to the present invention in processes selected from: fluid Catalytic Cracking, hydrocracking, hydroconversion, paraffin isomerisation, paraffin aromatisation, olefin oligomerisation, aromatic alkylation, aromatic disproportionation, aromatic isomerisation, MTG-MTO, hydration, hydrogenation, benzene hydroxylation, phenol hydroxylation, DeNOx stationary sources or synthesis of fine chemicals.

10

The present invention also comprises the use of the Ti-zeotype particle according to the present invention, in processes selected from: selective oxidation reactions, such as the hydroxylation of phenols, epoxidation of alkenes, and ammoxidation of ketones. Industrial production diphenols, cyclohexanone oxime and propylene oxide,

15 Conversion of Sugars to Lactic Acid Derivatives,

The present invention also comprises the use of the Sn-zeotype particle according to the present invention in processes selected from: Baeyer-Villiger reaction, Conversion of Sugars to Lactic Acid Derivatives.

20

The present invention also comprises the use of the Zr-zeotype particle according to the present invention in processes selected from: Conversion of Sugars to Lactic Acid Derivatives, cyclizations, hydrogenations

## 25 **Experimental details**

### Methods for characterisation – X-ray Powder Diffraction

XRPD is a widely used analytic method for structural characterization of crystalline materials. It is used to identify crystal structure and detect impurity phases. The method is based on diffraction, which occurs when an incident radiation interacts  
30 with an ordered solid and the wavelength of the electron magnetic radiation is in the same order as the distance between the crystal planes. Most often, the zeolite is analysed in the form of a powder and the obtained powder X-ray diffractogram can be used as a fingerprint unique to the particular crystalline phase. Due to the small amount of titanium in the sample, it will be difficult to discern by XRPD, whether TiO<sub>2</sub>

has formed. X-ray powder diffraction patterns (XRPD) was measured in transmission mode using Cu-K $\alpha$  radiation from a focusing quartz monochromator and a HUBER G670 Guinier camera.

5     Methods for characterisation – Scanning Electron Microscopy (SEM)

This analytic technique uses a finely focused high energy beam of electrons are is directed onto the surface of a sample. The electrons which are reflected by the surface and emitted secondary electrons, are detected to give a map of the surface topography of the sample. The samples may need to be applied with a conductive  
10     coating such as gold or graphite, to hinder local surface charging which leads to a decreased quality of SEM images [79].

Methods for characterisation – Transmission Electron Microscopy (TEM)

TEM is a microscopy technique in which a beam of electrons is transmitted through  
15     an ultra-thin specimen, interacting with the specimen as it passes through. An image is formed from the interaction of the electrons transmitted through the specimen; the image is magnified and focused onto an imaging device, such as a fluorescent screen, on a layer of photographic film, or to be detected by a sensor such as a  
20     CCD camera.

Methods for characterisation – Energy Dispersive X-ray Spectroscopy

In electron microscopy, the elements present in the sample emit characteristic X-rays due to the incident electron beam. These X-rays can be analysed to give a spectrum, and from there give both qualitative and quantitative results of the  
25     elements present [79]. Several precautions must however be made, as it is nigh impossible to get accurate quantitative results with this method on samples such as zeolites. This is because the accuracy of the spectrum is affected by the nature of the sample. X-rays are generated by any atom in the sample that is sufficiently excited by the incident electron beam. The X-rays are emitted in any direction, and  
30     so they may not all escape the sample. The likelihood of a X-ray escaping the sample, depends on the energy of the X-ray and the amount and density of material it has to pass through. This can result in reduced accuracy in porous and rough samples. As zeolites present are porous, the EDS results must be interpreted with caution, and are therefore only used qualitatively. SEM and EDS analysis were

performed on a Quanta 200 ESEM FEG. The calcined zeolite samples were placed on a carbon film.

#### Methods for characterisation – Nitrogen Physisorption

- 5 Key parameters for a solid catalyst is the accessibility of the active sites for reactants. A conventional way of measuring this is by physisorption of nitrogen gas at 77 K. This method provides information on both surface area and pore size distribution in the micro-, meso- and macroporous range. The method is a stepwise adsorption of N<sub>2</sub> which first forms a monolayer, as the pressure of N<sub>2</sub> increases
- 10 multilayers begin to form. The N<sub>2</sub> physisorption isotherms generated are very distinct, and classified into six types by IUPAC [80] which are presented in Figure 3. Nitrogen physisorption of microporous solids, such as zeolites, result typically in Type I isotherms. They are characterised by the limiting uptake, which happens at relative low pressure and is controlled by the accessible micropore volume, and not
- 15 the internal surface area. Type IV isotherms are most common when analysing mesoporous materials. The hysteresis loop between the adsorption and desorption branches, is a very characteristic feature for this type of isotherm, and is attributed to capillary condensation taking place in mesopores. Type II, III, V and VI are not commonly observed for zeolite materials, since they are typical for non-porous,
- 20 macroporous or materials with weak forces of adsorption [80].

Nitrogen adsorption and desorption measurements were performed at liquid nitrogen temperature (77 K) on a Micromeritics ASAP 2420. The samples were outgassed in vacuum at 300 °C, 16 hours prior to measurement. The total surface

25 areas were calculated according to the BET method. Pore size distributions were calculated with BJH method. External surface area, micropore area and micropore volume were determined by t-plot methods in the desorption branch. Total pore volume was calculated for pores around 80 nm width at  $p/p_0 = 0.97$ .

#### 30 Methods for characterisation – Diffuse Reflectance UV-Vis Spectroscopy

By exposing molecules to radiation in the ultraviolet-visible (UV-Vis) spectral region, spectroscopy can be applied to determine the concentration of an analyte. However, important characteristics of the sample are obtainable. It is possible to detect and determine the coordination environment of d-d transitions in the sample, and metal-

ligand complexes due to the specific energy required to excite them. However, in the case of powdered catalyst samples, the incident light can not penetrate the sample and is almost completely diffused. It is therefore not possible to use transmission spectroscopy, instead diffuse reflectance (DR) spectroscopy has to be applied.

- 5 Overall, this method can serve as a great asset in determining which titanium species is present in the produced catalysts. DR UV-Vis spectra were obtained with a CARY 5000 spectrometer employing spectralon® as internal standard.

#### Materials

- 10 Mesoporous silica (Merck, silica gel 100, particle size 0.063–0.200mm, pore diameter 15 nm, pore volume 1.15 ml/g), was used for the synthesis of mesoporous zeolites involving metal nanoparticles. The silica were dried at 80 °C for 24 hours prior to use. All other reagents were of reagent grade and used without further purifications: tetraethylorthosilicate (TEOS, 98 wt%, Aldrich), tetraethylorthotitanate  
15 (TEOT, 98 wt%, Aldrich), tetrapropylammonium hydroxide (TPAOH, 40 wt%, Fluka), hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>, 40 wt%, Aldrich).

#### Synthesis – propene based method

- The zeolites prepared by the new synthesis method disclosed in this application  
20 may be prepared by the following method using propene to form the carbon template coated zeolite, zeolite-like or zeotype precursor composition: First, 2.5 grams of silica is impregnated to incipient wetness with a metal nitrate solution, eg. nickel nitrate. This is allowed to stand at 80 °C overnight. The solid is subsequently placed in a tube oven and heated to 600 °C in argon flow. A gas mixture of 10%  
25 hydrogen in nitrogen is then led over for a total of 4 hours. The temperature is afterwards reduced to 550 °C under argon atmosphere. As an alternative to reducing the temperature to 550 °C under argon atmosphere, it may be increased to 700 °C still under argon atmosphere.
- 30 Propene gas is subsequently applied for 2 hours, afterwards a low flow of argon is led over, while the sample is allowed to cool off. Pure silica did not change colour during the procedure, while both nickel- and iron nitrate on silica were completely black after the treatment.

A mixture of 16.915 g 20% TPAOH, 4.25 ml water, 0.265 g NaOH and 0.095 g TEOT is prepared and stirred until a clear solution was obtained. The silica-carbon composite is added and left for 1 hour. The gel is then introduced into a stainless steel autoclave which is heated to 180 °C for 72 hours. Afterwards it is filtrated until  
5 the rinse water is neutral. The solid is left overnight at room temperature, followed by calcination at 550 °C for 24 hours. Zeolites made by this method are nominated Metal-C/SiO<sub>2</sub> ratio-TS-1, e.g. Ni-0.74-TS-1.

The above synthesized zeolite is in the following compared to other mesoporous  
10 catalysts prepared through carbon templating and desilication (results presented in figures 4-6 and 8-14). This is done to determine the influence the synthesis method has on active species in the catalyst, as well as the effect on the external surface area, and the ability to introduce mesoporosity in addition to the microporosity found in conventional zeolites.

15 In the following, conventional TS-1 catalysts are denoted TS-1 and mesoporous carbon-templated TS-1 (1% Ti) are denoted cTS-1. A conventional TS-1 that has been desilicated is denoted dTS-1 and TS-1 that has been prepared with BP-2000 and desilicated is named cdTS-1.

20

#### Characterization of Catalysts – Carbon Uptake with Propene Method

Several experiments were done to test the carbon loading with different parameters. After the carbon loading, several were synthesised to either HZSM-5, TS-1 or both. Table 1 shows the carbon uptake in a carbon-to-silica ratio (on weight basis) with  
25 different metals and parameters. Pure silica took up no amount of carbon, which also was proven by the absence of colour change after the propene procedure. The following zeolite synthesis was abandoned, as this would only create a conventional zeolite. The carbon uptake on nickel-SiO<sub>2</sub> was proven to be modifiable by both changing the metal loading and the flow of propene. An increase in nickel loading,  
30 also increased the carbon uptake, with a linear correlation. By changing the flow of propene, it was possible to modify the carbon uptake to some extent. An increase in flow from 51 ml/min to 67 ml/min resulted in a raise of C/SiO<sub>2</sub> ratio from 0.34 to 0.74. This was not increased further by another raise in flow speed. Iron showed a very

limited uptake with a C/SiO<sub>2</sub> ratio of 0.03. The silica was black after the propene treatment, confirming the uptake of carbon.

Samples	Metal Loading [wt%]	Propene Flow [ml/min]	C/SiO <sub>2</sub> Ratio [w/w]
SiO <sub>2</sub>	-	67	0
Ni-SiO <sub>2</sub>	1%	51	0.34
Ni-SiO <sub>2</sub>	1%	67	0.74
Ni-SiO <sub>2</sub>	1%	85	0.75
Ni-SiO <sub>2</sub>	2%	67	1.18
Ni-SiO <sub>2</sub>	5%	67	2.13
Fe-SiO <sub>2</sub>	1%	67	0.03

5 Table 1: Carbon uptake of silica with different metal loading and propene flow.

#### Characterization of Catalysts – XRPD

For comparison of crystallinity of the zeolite catalysts, XRPD patterns were recorded after synthesis and subsequent calcination. Patterns for all synthesised TS-1 catalysts are presented in Figure 4. It is clear that the zeolite samples contain highly crystalline structure, with no impurities or amorphous phase present. It is difficult to discern if titanium is present in other confirmations than inside the framework, as the titanium content is very low. In addition, all patterns match the pattern of silicalite-1, confirming the MFI structure. The Ni-0.74-TS-1 catalyst produced by the synthesis method disclosed in this application (nickel-propene method), also underwent XRPD analysis. The result is present in Figure 5. The catalyst exhibit the same characteristic pattern as samples with MFI structure. In addition, no amorphous phase or impurities were found present, and the sample was highly crystalline.

#### 20 Characterization of Catalysts – Scanning Electron Microscopy (SEM)

All synthesised catalyst underwent analysis by SEM. This was done to investigate the morphology of the produced catalysts. In Figure 6 conventional and mesoporous TS-1 are compared to the desilicated counterparts. Conventional TS-1, Figure 6a, shows clearly defined cubic coffin shaped crystals with sizes of 0.2-0.4  $\mu\text{m}$ . With crystals in this size range, the diffusion limitations have been decreased to a minimum, without introducing mesopores. Desilicated TS-1 are shown in Figure 6b. It shows an agglomerate of smaller crystals, with no clear consistent structure or

size. Compared to the conventional TS-1, the mesoporous sample in Figure 6c is much bigger, with crystal sizes in the range of 1.5-2.5  $\mu\text{m}$ . While the surface for the conventional TS-1 is very smooth, the mesoporous sample exhibits a more "sponge"-like shape. The desilicated mesoporous TS-1, Figure 6d, shows some of the same characteristics as the other desilicated sample. These similarities are the agglomeration of smaller crystals, and no clear structure or size. The shape of the original mesoporous sample can however faintly be seen.

SEM images of the propene treated nickel and iron samples are shown in Figure 7. The reason for the higher carbon uptake on the nickel samples are clear here. Several carbon nanofibers are present on the nickel sample, and absent on the iron sample. This was expected as, nickel is known for creating carbon whiskers at high temperatures in the presence of hydrocarbons [42]. To examine whether the iron nanoparticles were unchanged within the zeolite and encapsulated in carbon, TEM analysis will have to be done. TEM analysis will also be interesting, as to determine the size of the produced nanoparticles, both before and after synthesis.

Figure 8 is a picture of the titanium containing zeolites prepared through the coking of nickel nanoparticles. The sample presented in Figure 8, has a  $\text{C}/\text{SiO}_2$  ratio = 0.75, and showed mesoporosity visible with SEM. In addition, all silica was also converted to zeolites.

#### Characterization of Catalysts – Energy Dispersive X-ray Spectroscopy

EDS was used to qualitatively determine the elements present in the samples. All TS-1 catalysts synthesised showed the presence of titanium, silicon and oxygen. Furthermore the samples prepared through coking of nickel nanoparticles, also showed presence of nickel. To get an exact value of the nickel present in the sample, a method consisting of dissolution of the zeolite, followed by Inductively Coupled Plasma (ICP) could be applied.

#### Characterization of Catalysts – Nitrogen Physisorption

The textural properties of the synthesized materials were determined by adsorption-desorption analysis with nitrogen. The observed SBET, external surface areas,  $S_{\text{ext}}$ , micropore and total pore volumes are collated in Table 2. The BET value is less for

cdTS-1 and cTS-1. Logically the samples exhibit increasing external surface area after the introduction of mesoporosity. cTS-1 has the highest external surface, dTS-1 somewhat lower, and cdTS-1 curiously has a value which corresponds with the average of cTS-1 and dTS-1. The same is the case for the micropore volumes.

- 5 Figure 9 shows the isotherms of the samples. According to the IUPAC classification of physisorption isotherms, the conventional TS-1 has a type I isotherm with a sharp transition in the adsorption branch at  $P/P_0 < 0.1$  and almost no adsorption at intermediate relative pressures. This is typical for purely microporous materials such as zeolites.

10

At  $P/P_0 > 0.9$  further nitrogen uptake takes place due to the interparticle adsorption within the voids between the small zeolitic particles as observed in the SEM analysis for conventional TS-1. cTS-1, dTS-1 and cdTS-1 exhibit the type IV isotherms with clearly visible hysteresis loops, which are typical for mesoporous materials. The mesoporous samples created by carbon templating of TS-1, present hysteresis loops at  $P/P_0 > 0.86$  and can be attributed to the interparticle adsorption within the voids formed between the zeolitic particles, or more likely due to creation of some very large pores, which would be in line with observation of large, SEM visible porosity in the cTS-1 sample. dTS-1 (and cdTS-1 to a smaller extent) show smaller hysteresis loop closing at  $P/P_0 > 0.42$  with less generation of mesopores compared to micropores. These could be from the voids existing between the nanocrystallites due to the desilication, but they are more likely to originate from the so-called TSE-effect [81, 82] where capillary evaporation during desorption occurs via a hemispherical meniscus, separating the vapour and the capillary condensed phase [83].

25

Sample	$S_{\text{BET}}$ $\text{m}^2/\text{g}$	$S_{\text{ext}}$ $\text{m}^2/\text{g}$	$V_{\text{Micro}}$ $\text{cm}^3/\text{g}$	$V_{\text{p}}$ $\text{cm}^3/\text{g}$
TS-1	390	166	0.0915	0.224
dTS-1	346	225	0.0498	0.478
cTS-1	367	136	0.0981	0.448
cdTS-1	353	182	0.0731	0.622

Table 2: Nitrogen physisorption data for the investigated catalysts.

Barrett-Joyner-Halenda (BJH) analysis of desorption branch further indicate secondary a mesopore distributions in the TS-1 derived catalysts. This mesoporosity is created at the expense of the decrease of micropore volume as seen in Table 2, especially for cTS-1 and cdTS-1, and an increase of the external surface compared to the value of TS-1 as mentioned above. For cTS-1 calcination of carbon template create mesoporous of around 19 nm and around 59 nm for cdTS-1. The dTS-1 catalyst exhibits mesopores around 60 nm but in lesser amount as shown in figure 10.

The zeolite prepared trough coking of nickel nanoparticles, Ni-0.74-TS-1, was also characterised with nitrogen physisorption. Figure 11 shows the adsorption/desorption isotherms of the zeolite. The sample shows a clear type IV isotherm, with hysteresis loops at  $P/P_0 > 0.80$ , most likely to originate from mesopores. The hysteresis loop around  $P/P_0 > 0.18$ , has still yet to be assigned to a structural property. The BJH pore size distribution, Figure 12, confirms the presence of mesopores of the same size (19 nm) as the carbon templated TS-1, but in a much smaller magnitude. In addition, the size of the micropores are slightly smaller than the conventional TS-1, and similar to the TS-1 zeolites prepared by carbon templated. The mesoporosity of the Ni-0.74-TS-1 is also confirmed by the  $V_p$  result presented in Table 3. With a value of  $0.323 \text{ cm}^3/\text{g}$ , this is nearly 1.5 times greater than the conventional TS-1 synthesised. In addition, the external surface area of Ni-0.74-TS-1, is also larger, at  $189 \text{ m}^2/\text{g}$  compared to  $166 \text{ m}^2/\text{g}$  of the conventional TS-1.

Sample	$S_{\text{BET}}$ $\text{m}^2/\text{g}$	$S_{\text{ext}}$ $\text{m}^2/\text{g}$	$V_{\text{Micro}}$ $\text{cm}^3/\text{g}$	$V_p$ $\text{cm}^3/\text{g}$
Ni-0.74-TS-1	400	189	0.0854	0.323

Table 3: Nitrogen physisorption data for the synthesised Ni-0.74-TS-1.

#### Characterization of Catalysts – Diffuse Reflectance UV-Vis spectroscopy

Figure 13 shows the results of the DR-UV-Vis spectroscopy. TS-1 shows a maximum at  $47600 \text{ cm}^{-1}$  (210 nm), which is characteristic from the charge transfer of

oxygen 2p electron to the empty 3d orbit of framework Ti species in tetrahedral coordination. This band is known as a fingerprint of tetrahedrally coordinated  $\text{Ti}(\text{OSi})_4$  species in titanium silicate frameworks. The slightly shift to higher wavelengths. at ca.  $45500\text{ cm}^{-1}$  (220 nm) for the desilicated samples suggests the simultaneous presence of tetrahedral tripodal  $\text{Ti}(\text{OSi})_3\text{OH}$  and tetrapodal  $\text{Ti}(\text{OSi})_4$ . This might be a due to an increased surface density of  $\text{Ti}^{4+}$ , due to the desilication process. This effect is only apparent in the desilicated samples, cdTS-1 and dTS-1.

Furthermore, dTS-1 shows a broad band at  $38400\text{--}33300\text{ cm}^{-1}$  (260–300 nm) that can be attributed to the partially polymerized hexacoordinated non-framework Ti species, which contain Ti-O-Ti bonds [84, 85]. This strongly suggest a densitification of titania species, most likely on the outside of the zeolite framework. In addition, cTS-1 and cdTS-1 also shows a broad band between  $31250\text{--}29400\text{ cm}^{-1}$  (320–340 nm), which is typical for larger extraframework  $\text{TiO}_2$  particles with a structure similar to anatase. This suggest that the carbon-templating technique might also interfere with the active titania sites to some degree, perhaps by provoking some agglomeration of titania species near the mesopore channels, which could be thought to occur from the creation of hotspots during the carbon burnout. Overall, the titania species appear less harmed by the carbon-template method compared to the desilication method.

For an easier comparison, TS-1 is also shown in Figure 14. Ni-0.74-TS-1 shows a maximum at around  $47600\text{ cm}^{-1}$  (210 nm), just as conventional TS-1. In addition it shows the same tendency to absorb in the broad band between  $31250\text{--}29400\text{ cm}^{-1}$  (320–340 nm), just like the other carbon templated zeolites.

#### Synthesis – methane based method

As an alternative to the propene based synthesis shown and discussed above, the zeolites prepared by the new synthesis method disclosed in this application may be prepared by the following method using methane to form the carbon template coated zeolite, zeolite-like or zeotype precursor composition: First, 5 grams of silica are impregnated to incipient wetness with a nickel nitrate solution. The resulting materials typically contained around 2 wt% of Ni metal. This is allowed to stand overnight. The solid is then placed in a tube oven and heated to  $600\text{ }^\circ\text{C}$  in argon

flow, with a subsequent change of gas to 10% hydrogen in nitrogen for 4 hours. The temperature is reduced to 550 °C under argon. As an alternative to reducing the temperature to 550 °C under argon atmosphere, it may be increased to 700 °C still under argon atmosphere.

5

Methane gas is then applied for between 10 minutes and up to 12 hours. Preferably, methane is added for between 2-8 hours, or approximately 6 hours if the temperature is kept at 550 °C. If the temperature is kept at 700 °C, methane is normally applied for a shorter time of 10 minutes to 4 hours, or for 2-3 hours.

10

Afterwards, the oven is cooled to room temperature with a flow of Ar.

In a 20 ml Teflon beaker 0.5 g of the materials from above are impregnated with 2.95 ml of 20% TPAOH (tetrapropylammonium hydroxide) solution. 10-20 ml of water is introduced to a 300 ml stainless steel autoclave. The Teflon beaker is placed in the water in the bottom of the autoclave. The closed autoclave is heated to 180 °C for 72 hours. Afterwards, the solid is washed with demineralized water. The zeolite/carbon composition is then heated to 550 °C for 24 hours to remove the carbon.

15

20 The TEM image of the above zeolite produced using methane, where the materials is heated to 550 °C under argon before methane gas is added, is displayed in Figure 15.

The SEM image of the above zeolite produced using methane, where the material is heated to 700 °C under argon before methane gas is added, is displayed in Figure 16.

25

In Figures 17a and Figures 17b, the XRPD pattern of MFI zeolite synthesized using methane is displayed, where Figure 17a represents a synthesis method, where the material is heated to 550 °C under argon before methane gas is added and Figure 17b represents a synthesis method, where the material is heated to 700 °C under argon before methane gas is added.

30

As can be seen when comparing Figure 5 with Figure 17a and Figure 17b, very little variation is observed in the XRPD pattern depending on which gaseous hydrocarbon that is used in the synthesis and at which temperature the sample is heated.

**Claims**

1. A method for producing zeolite, zeolite-like or zeotype particles comprising the steps of:
  - 1) Adding one or more metal precursors to a silica or alumina source;
  - 5 2) Reducing the one or more metal precursors to form metal nanoparticles on the surface of the silica or alumina source;
  - 3) Passing a gaseous hydrocarbon, alkyl alcohol or alkyl ether over the silica or alumina supported metal nanoparticle to form a carbon template coated zeolite, zeolite-like or zeotype precursor composition;
  - 10 4a) Adding a structure directing agent to the carbon template coated zeolite, zeolite-like or zeotype precursor thereby creating a zeolite, zeolite-like or zeotype gel composition;
  - 4b) Crystallising the zeolite, zeolite-like or zeotype gel composition by subjecting said composition to a hydrothermal treatment;
  - 15 5) Removing the carbon template and structure directing agent and isolating the resulting zeolite, zeolite-like or zeotype particles.
2. A method for producing zeolite, zeolite-like or zeotype particles according to claim 1, wherein the carbon template coated zeolite, zeolite-like or zeotype precursor composition of step 3 is used directly in step 4a without removing the silica or alumina source.
- 20 3. A method for producing zeolite, zeolite-like or zeotype particles according to any preceding claim, wherein the one or more metal(s) is selected from the group consisting of group 4 elements, group 6 elements, group 7 elements, group 8 elements, group 9 elements, group 10 elements, group 11 elements or group 12 elements or mixtures thereof.
- 25 4. A method for producing zeolite, zeolite-like or zeotype particles according to preceding claim, wherein the one or more metal(s) is selected from the group consisting of titanium, osmium, iridium, platinum, ruthenium, palladium, rhodium, rhenium, copper, nickel, iron, cobalt, silver, gold, cadmium, molybdenum or mixtures thereof.
- 30

5. A method of producing a zeolite, zeolite-like or zeotype particle according to any preceding claim, the method further comprising adding an Al, Sn Ti, Zr or Ge source during step 4a.
- 5 6. A method for producing zeolite, zeolite-like or zeotype particles according to any preceding claim, wherein the hydrocarbon is selected from aliphatic hydrocarbons having 1 to 8 carbon atoms, having 1 to 3 carbon atoms, alkenes having 2 to 6 carbon atoms, aromatic hydrocarbons having 6 to 10 carbon atoms and cyclic hydrocarbons having 3 to 8 carbon atoms.
- 10 7. A method for producing zeolite, zeolite-like or zeotype particles according to claim 6, wherein the hydrocarbon is selected from methane, propene, xylene or benzene.
- 15 8. A method for producing zeolite, zeolite-like or zeotype particles according to any preceding claim, wherein the hydrothermal treatment comprise that the zeolite, zeolite-like or zeotype gel composition is heated to temperatures between 70 and 300 °C, preferably at 180 °C, under an autogeneous pressure in an autoclave or open flask for 24 hours or more.
- 20 9. A method for producing zeolite, zeolite-like or zeotype particles according to any preceding claim, wherein the one or more metal metals precursors is added to the silica or alumina source in an amount of 5 to 20 wt %, from 0.5 to 5 wt %, from 0.5 to 2 wt %, or around 1 wt % during step 1.
- 25 10. A zeolite, zeolite-like or zeotype particle manufactured by the method according to any one of the claims 1-9 with a crystal structure comprising one or more encapsulated metal nanoparticles.
- 30 11. A zeolite, zeolite-like or zeotype particle according to claim 10, wherein the particle is a hierarchical mesoporous zeolite or zeotype particle.
12. A zeolite, zeolite-like or zeotype particle according to claim 10 or 11, wherein the amount of metal nanoparticles are in the range of 0.1 to 25 wt%, in the

range from 0.5 to 20 wt%, from 0.5 to 10 wt%, from 0.5 to 5%, from 1.0 to 5 wt %, from 1 to 2 wt %, or around 1 wt %.

- 5 13. A zeolite, zeolite-like or zeotype particle according to any one of the claims 10-12, wherein the one or more encapsulated metal nanoparticles comprise one or more metal(s) selected from the group consisting of group 4 elements, group 6 elements, group 7 elements, group 8 elements, group 9 elements, group 10 elements, group 11 elements or group 12 elements or mixtures thereof.
- 10 14. A zeolite, zeolite-like or zeotype particle according to any one of the claims 10-13, wherein the one or more encapsulated metal nanoparticles comprise one or more metal(s) selected from the group consisting of titanium, osmium, iridium, platinum, ruthenium, palladium, rhodium, rhenium, copper, nickel, iron, cobalt, 15 silver, gold, cadmium, molybdenum or mixtures thereof.
- 20 15. A zeolite, zeolite-like or zeotype particle according to any one of the claims 10-14, the zeolite, zeolite-like or zeotype particle comprising an Al, Sn, Ti, Zr or Ge source in the framework of the crystal structure.
- 25 16. Use of the zeolite particle according to any one of the claims 10-15 in processes selected from the group of: fluid Catalytic Cracking, hydrocracking, hydroconversion, paraffin isomerisation, paraffin aromatisation, olefin oligomerisation, aromatic alkylation, aromatic disproportionation, aromatic isomerisation, MTG-MTO, hydration, hydrogenation, benzene hydroxylation, phenol hydroxylation, DeNOx stationary sources or synthesis of fine chemicals.
